Commentary

Clinical reasoning in osteopathy — More than just principles?

Oliver P. Thomson, Nicola J. Petty, Ann P. Moore

Keywords: Osteopathy, Osteopathic medicine, Clinical reasoning, Knowledge, Decision-making, Evidence-based medicine

Abstract

Clinical reasoning is an integral part of clinical practice, and importantly for osteopaths, encompasses more than just the formulation of a diagnosis. With the advent of evidence-based practice health professionals are required to make explicit the strategies behind their clinical decisions. With many other health professions taking a critical view of their models of practice, there is an equal requirement for the osteopathic profession to reflect on and improve the transparency of clinical practice models used in osteopathy. This paper discusses the role of clinical reasoning in professional practice and the existing research in a number of health professions. It considers the need of such research in the osteopathic profession, and goes on to outline the methods by which clinical reasoning can be made visible through research.

1. Introduction

With the number of osteopaths in the UK exceeding over 4000, osteopaths are increasingly being seen as core deliverers of neuromusculoskeletal care, particularly in the management of people with non-specific low back pain. Osteopaths in the UK are autonomous practitioners who require a wide-ranging knowledge and skill base, reflected by the range of musculoskeletal and non-musculoskeletal conditions which they encounter.

The advent of the Department of Health Quality Agenda in 1998 was one of the several forces to set about a shift to evidence-based practice (EBP). EBP has placed pressure on health professions to assure the public of rigorous, scientific practice. Part of this accountability is to make explicit and demystify aspects of clinical practice for the purposes of scrutiny, critique and further investigation, by those within the profession as well as consumers, external stakeholders and other health professions. One aspect of clinical practice which remains poorly understood is the processes by which practitioners make diagnostic, therapeutic and management decisions with their patients, termed clinical reasoning. Once it is made more explicit through research, clinical reasoning in osteopathic practice can begin to be defined, developed and explored. Explicating osteopathic clinical reasoning is therefore necessary to provide the profession, educators and external stakeholders with a greater understanding of osteopathic clinical practice.

2. Defining clinical reasoning

The term ‘clinical reasoning’ has different meanings to different people, and a range of terms exist in the literature to describe it. This variation in terminology represents a historical change in the focus of health professions, and a movement toward the biopsychosocial model of care. At present there is little consensus of a universal definition, rather, the term appears to be largely conceptualised according to the professions’ values. One of the earliest descriptions and one that many osteopaths may be familiar with is the term clinical problem-solving. Clinical problem-solving has its origin in the medical profession and was used to describe the cognitive process practitioners employed to ‘solve’ (the often unsolvable!) patients’ problems. As a term ‘clinical problem-solving’ fails to describe the complex process of clinical reasoning which occurs in the osteopathic (and other health professionals) patient encounter for two main reasons: 1) it somewhat narrowly denotes that the clinicians’ main objective is to find and solve problems, by formulating diagnoses and differential diagnoses, with little regard to the treatment and management aspects of the patient; 2) Considering the patient as a ‘problem’ or series of ‘problems’ does little to empower the patient, nor does it add to the notion of including the patient in the decision-making process. The concept of problem-solving emerged during a period when there was great emphasis on the
disease, rather than the patient with the disease. For that reason the concept may be too centered on diagnosis formulation, in order for it to be seamlessly transferred to allied health professions, including osteopathy.

Research into health professions over the past 25 years has vastly expanded upon the early descriptions of clinical reasoning, in line with contemporary models of health and disability.

This research has shown clinical reasoning to be a dynamic process, which occurs throughout the patient encounter, and moves beyond the point of diagnosis formation. Clinical reasoning is now viewed as “a process in which the clinician, interacting with significant others (client, caregivers, healthcare team members), structures meaning, goals and health management strategies based on clinical data, client choices, and professional judgement and knowledge.” This much broader description has elements which are particularly suited for its use in the osteopathic context of healthcare: Firstly, it incorporates the patient ‘voice’ so that they may collaborate with the practitioner (and other health professionals) to achieve improved health status; and secondly, it recognises that clinical reasoning is a dynamic process which is informed by different sources and types of knowledge.

Clinical reasoning has been described as a ‘bridge between practice and knowledge’ (P. 11). Without such a bridge developed from research, the credibility of osteopathy and its claim as a ‘profession’ may be challenged. Research into clinical reasoning in osteopathy will contribute to a platform for future work exploring the nature of osteopathic expertise, and the methods by which novice osteopathic practitioners may attain such expertise, enabling them to safely and effectively treat their patients.

3. Clinical reasoning in other health professions

Clinical reasoning involves complex processes (also termed strategies) through which clinicians make diagnostic, treatment and management decisions about patients and crucially with their patients, and is regarded as the foundation of professional clinical practice. Importantly, clinical reasoning encompasses more than just the process of reaching a diagnosis, which while pivotal, is just part of a range of clinical reasoning strategies at a clinicians’ disposal. Research in the health sciences has identified the clinical reasoning strategies used in different health professions. While all health professions tend to share common core components (such as diagnostic, procedural and narrative reasoning), the approach each profession takes to clinical reasoning varies, and a number of different clinical reasoning strategies have been identified through research or proposed theoretically: in nursing, occupational therapy, and in physiotherapy.

Table 1 illustrates the clinical reasoning strategies identified in a range of health professions.

Researchers in occupational therapy have identified that occupational therapists tend to employ three major clinical reasoning strategies during a patient encounter: procedural, interactive and conditional reasoning strategies. Occupational therapists are often described as having a “three track mind” when using these three strategies either alone or in unison. In the nursing profession, the research literature emphasises ethical reasoning, which involves making decisions or judgements about moral or ethical dilemmas.

Researchers began investigating the clinical reasoning used by physiotherapists during a patient encounter; procedural, interactive and conditional reasoning strategies. The strategies identified in occupational therapy correspond with reasoning strategies identified in existing physiotherapy research and previously in other health professions: diagnostic reasoning (medicine), procedural, interactive, and predictive (or conditional) reasoning (occupational therapy), collaborative reasoning and teaching as reasoning (physiotherapy), and ethical reasoning (nursing).

4. Clinical reasoning in osteopathy – a need for research

Many-a-clinic tutor (and osteopathic student) will be familiar with the situation whereby the student hypothetically-deductively ‘does the rounds’ of possible diagnoses…. “disc, facet joint… sacroiliac joint etc”. As clinicians, we are all familiar with formulating a diagnostic hypothesis, then confirming or refuting it by further investigation, be it pain provocation, passive joint motion, neurological or orthopaedic tests. Experienced practitioners may travel through the process of diagnosis formulation swiftly, efficiently and almost unconsciously, this is termed pattern recognition. Hypothetico-deductive reasoning and pattern recognition, are well recognised diagnostic reasoning strategies used by a number of health professions, including medicine, physiotherapy and osteopathy. Hypothetico-deductive reasoning and pattern recognition help to describe how, as practitioners we arrive at a diagnosis, which is a fundamental ‘step’ in clinical practice. However, little is known about the clinical reasoning strategies that occur during the ongoing treatment and management aspects of the osteopathic patient encounter. Returning to the description of clinical reasoning offered earlier, how does an osteopath navigate a course from the formulation of a diagnosis, to the treatment (structuring of treatment plans, setting of goals and implementation of health management strategies) of their patient? Is it likely to be more than just the application of osteopathic principles.

While osteopaths throughout the years have relied upon osteopathic principles to guide practice, without research available to describe the actual nature of clinical reasoning used in osteopathy this remains an assumption. While the works of the early osteopathic pioneers have shaped the osteopathic profession, it is not satisfactory to continue to rely on such a limited body of work from a small number of individuals. By doing so we cannot claim to be

a progressive and reflective profession. By definition, a profession is required to possess a discrete body of knowledge to be used within its teaching and practice, which is vital for academic credibility and legitimacy. An understanding of a health professionals’ clinical reasoning forms part of this body of knowledge, illuminating what they do, how they do it and why they do it.

Not possessing an understanding of clinical reasoning has not only educational, professional and political ramifications, but also impacts practicing osteopaths, at the ‘coal face’ of the profession. Osteopaths need to be able to explain the reasons behind their treatment choices to their patients, and clinical reasoning provides the conduit for this to occur effectively. Moreover, clinical reasoning is a complex process, and osteopaths have to treat and manage patients with complex problems. Therefore, sound clinical reasoning is required for osteopaths to effectively manage these patients. Understanding the complexity of osteopathic clinical reasoning will enable osteopaths to reason more effectively.

In order to provide high quality services to members of the public, osteopaths need evidence to support all aspects of their practice. Today as the demands of an overstretched healthcare system increases, the clinical reasoning of all healthcare professionals must be placed within the context evidence-based practice (EBP). In recognising that the ultimate goal of EBP is to inform clinical decisions, EBP should perhaps, and importantly for this discussion, be more suitably called ‘evidence-informed decision-making’.

The application of these research findings should not occur in isolation, but rather in the context of patient-centred clinical reasoning. Clinical reasoning research would provide the necessary framework by which osteopaths can integrate this research with different forms of knowledge, in a particular way for a particular patient, constituting what is known as professional artistry.

In the UK there is no ‘core’ curriculum in place in osteopathic education, but there are ‘Standards of Proficiency’ for osteopathic education and practice, set by the General Osteopathic Council. Interestingly, this document is explicit in stating clinical reasoning as an ‘area of capability’ for the ‘safe and competent practice of osteopathy’ (P. 4). Without a body of research to explain what clinical reasoning in the context of osteopathy ‘looks like’, means this area of competence is largely left up to the interpretation of osteopaths and educators alike. Clinical reasoning has been widely acknowledged as a vital part in health profession education and is the nucleus of professional practice. Without knowledge of clinical reasoning processes in osteopathy the profession will have difficulty in characterising its professional approach, thereby placing an obstacle for inter-professional learning and understanding. Research is necessary to provide an understanding of the nature and scope of clinical reasoning used by osteopaths, giving an important and much needed insight into aspects of osteopathic practice which have not been investigated to date. The ability of the osteopathic profession to articulate its clinical reasoning will facilitate the understanding of facets of clinical practice, such as professional artistry, expertise and how practitioners learn and develop these skills in clinical practice.

Identifying the nature of the clinical reasoning strategies employed in osteopathic practice, is an important part of addressing issues regarding professional scope and values, and enabling questions such “How do clinical reasoning processes employed by osteopaths compare and contrast with other health professions?” “How do novice and experienced osteopaths clinically reason?” to be answered. Whilst osteopathic patient approaches vary between practitioners, it is often claimed that osteopathic practice is underpinned by the osteopathic principles derived through the seminal work of A.T. Still and other osteopathic scholars, yet little is known about how these principles might drive osteopathic decision-making in practice. What role do the osteopathic principles play in clinical reasoning, if any?

To give an example, an osteopath may bear in mind the principle ‘the rule of the artery is supreme’ during the treatment of a patient with an entrapment neuropathy at the wrist. They may mobilise and manipulate the soft tissues and joints of the thoracic outlet and the cervicothoracic spine with the aim to enhance the fluid dynamics of the upper extremity. They may also offer postural, exercise and lifestyle advice for the longer term management of the patient. However, the ‘rule of the artery’ (or a combination of any of the other osteopathic principles) is unable to fully explain the subtle and complex interplay of different clinical reasoning processes used in the treatment and management of a patient such as this. This is where clinical reasoning research can help bridge the gap between osteopathic principles and practice. Research would help explain some of the hidden components contained within the ‘black box’ of the osteopath-patient encounter, making it available for current practitioners to learn from, for educators to teach from and for researchers to further expand upon.

5. How to make the invisible visible? – clinical reasoning research

Researchers across the health professions have been attempting to understand the process of clinical reasoning for the past three decades, with the majority of the research focusing primarily on the process practitioners use to arrive at a diagnosis. Research into clinical reasoning has used both qualitative and quantitative methodological approaches to data gathering and analysis. The pioneers in clinical reasoning research operated predominantly in the empirico-analytical paradigm, using both qualitative and quantitative data. Research into clinical reasoning is faced with numerous difficulties; with the main factor that clinical reasoning is a cognitive process and therefore resides in the mind of the clinician, which is largely hidden from observers. With this difficulty in mind, a range of research methods, operating in different research paradigms have been used to investigate the different aspects of clinical reasoning. Quantitative approaches may be better suited to limit, test or compare aspects of clinical reasoning, for example ‘do experts or novices generate more differential diagnoses?’, while qualitative methods will illuminate factors which can help explain an individual’s clinical reasoning (for example, how do osteopaths structure their treatment plan in private practice?).

Early research into clinical reasoning was mainly conducted by the medical profession using qualitative methods, leading to the development of hypothetico-deductive methods of diagnostic reasoning. However, other health professions, wanting to gain a deeper understanding of their professional practice began using qualitative research methodologies as a way to explore complex and often discrete aspects of their discipline, within the context of ‘real life’ clinical practice. For example occupational therapists using ethnography, physiotherapists using grounded theory and nurses using hermeneutics. These researchers were able to capture more fully the subtle, dynamic and previously hidden aspects of the patient—practitioner interaction. Observation and/or video-recording of treatment sessions, interviews with practitioners and patients, written materials from the practitioners (for example reflective diaries) have served as data collection methods in research into clinical reasoning all with varying strengths and weaknesses.

The issues and limitations surrounding the methods of acquiring clinical reasoning data are numerous and pose a direct challenge to researchers. Interviewing practitioners is one commonly chosen method, and can be used as a standalone in-depth method, or can occur following the observation of a practitioner—patient encounter (termed ‘debriefing’) or during a ‘live’ patient encounter (termed ‘think aloud’). One major limitation of the debriefing/interview
method is the possibility of subjects to (intentionally or unintentionally) reflect on their thinking, thus providing a 'rehearsed' or altered verbal report in accordance with what they think the researcher might like to hear.65 Conducting the debriefing immediately after the observation, and the researcher carefully reassuring the practitioner that there are no right or wrong answers, aim to lessen this limitation.66

Observation of the patient encounter, either directly in person or indirectly via the use of video recording, is a valuable tool in clinical reasoning research, producing 'rich' data on specific aspects of practice. However, the awareness of a research participant under study poses problems for using observation as a method of collecting data. A practitioner (or patient!) conscious of being observed may behave in a way that they may not do normally, thereby confounding the collected data. This 'reactive' or 'guinea pig' effect67 will be present to some degree in all research utilising overt observation methods, but recently the novel use of a head-mounted camera has been used to minimise the effect.71

6. Summary

Clinical reasoning must and does occur within every health profession. To understand more about the basis of this clinical reasoning can only help to strengthen the profession's position within healthcare practice. Currently little is known about clinical reasoning processes within osteopathy, and other professions are gaining momentum in this area of theoretical underpinning for their health profession related work. Once clinical reasoning models are established for osteopathy this will help to describe the profession in terms of the competing areas of practice. Throughout the history of osteopathy, numerous theories and models of practice have been proposed and taught. However in light of contemporary research into clinical reasoning the role that these models and underlying principles play in clinical reasoning, is yet to be investigated. In view of a growing number of osteopaths and a healthcare landscape that demands a reflective and evidence-informed approach to practice, an exploration of these issues is timely and necessary for the further development of osteopathy as a profession. Developing an understanding of clinical reasoning from an osteopathic perspective will enable existing practitioners to refer to a body of research, and thereby facilitate them to reason more effectively. The osteopathic profession should build on the progress made by many other health professions. Research is needed to address some of the issues discussed in this article, and thereby help to illuminate the clinical reasoning of this osteopath.
